Department of General Pediatrics, Heinrich-Heine-University, Düsseldorf, Germany

Abstract Long-chain acylcarnitines accumulate in long-chain fatty acid oxidation defects, especially during periods of increased energy demand from fat. To test whether this increase in long-chain acylcarnitines in very long-chain acyl-CoA dehydrogenase (VLCAD−/−) knock-out mice correlates with acyl-CoA content, we subjected wild-type (WT) and VLCAD−/− mice to forced treadmill running and analyzed muscle long-chain acyl-CoA and acylcarnitine with tandem mass spectrometry (MS/MS) in the same tissues. After exercise, long-chain acyl-CoA displayed a significant increase in muscle from VLCAD−/− mice [C16:0-CoA, C18:2-CoA and C18:1-CoA in sedentary VLCAD−/−: 5.95 ± 0.33, 4.48 ± 0.51, and 7.70 ± 0.30 nmol · g−1 wet weight, respectively; in exercised VLCAD−/−: 8.71 ± 0.42, 9.03 ± 0.93, and 14.82 ± 1.20 nmol · g−1 wet weight, respectively (P < 0.05)]. Increase in acyl-CoA in VLCAD-deficient muscle was paralleled by a significant increase in the corresponding chain length acylcarnitine. Exercise resulted in significant lowering of the free carnitine pool in VLCAD−/− muscle. This is the first study demonstrating that acylcarnitines and acyl-CoA directly correlate and concomitantly increase after exercise in VLCAD-deficient muscle.—ter Veld, F., S. Primassin, L. Hoffmann, E. Mayatepek, and U. Spiekerkoetter. Corresponding increase in long-chain acyl-CoA and acylcarnitine after exercise in muscle from VLCAD mice. J. Lipid Res. 2009, 50: 1556–1562.

Supplementary keywords β-oxidation • very long-chain acyl-CoA dehydrogenase • acyl-coenzyme A • acylcarnitine

Very-long-chain acyl-CoA dehydrogenase (VLCAD or ACADVL, EC 1.3.99.3) catalyzes the first step in the β-oxidation pathway of long (C14 or longer) chain fatty acids. Deficiency of this enzyme severely impairs the oxidation of long-chain fatty acids (1). Mutations in the VLCAD gene lead to clinical symptoms in children and young adults. Physiological stressors such as fasting, exercise, and viral illnesses are triggers of disease crises (2, 3). Neonatal screening programs (4, 5) have, however, drastically improved long-term survival and a great number of patients have remained asymptomatic with proper preventive measures during the first years of life (4). However, as there is no prevalent VLCAD mutation and VLCAD mutations cannot be correlated to residual VLCAD activity, as measured in fibroblasts or lymphocytes, the late-onset disease phenotype varies greatly (6). Neonatal screening programs are thus identifying more and more patients carrying VLCAD mutations whose clinical outcome cannot be predicted at the time of diagnosis. Therefore, the effect of possible disease triggers, such as exercise-stress, and their resulting metabolic phenotype (i.e., acylcarnitine and/or acyl-CoA accumulation) need to be identified.

With the generation of a transgenic VLCAD-deficient mouse (VLCAD−/−) that displays a stress-induced phenotype similar to that of humans (7, 8), new possibilities arise to study the effect of physiological stressors, such as fasting and exercise, at tissue level. In these mice it was shown that they have impaired Ca2+ handling (9) and heart rate dysfunction (10). VLCAD−/− soleus muscle showed an increase in mitochondrial density, and mitochondria were more heterogeneous in size and appeared disorganized (7). Similar to VLCADD-patients, the metabolic VLCAD−/− mouse phenotype displays an accumulation of fat droplets (7) and long-chain acylcarnitines (11) in muscle.

Acylcarnitines are known to have unspecific cytotoxic effects (12, 13) and accumulate in VLCAD-deficient patients during crisis due to insufficient oxidation capacity of long-chain fatty acids (14). As cytosolic carnitine palmitoyltransferase (CPT) I and mitochondrial CPT-II catalyze the forward and reverse conjugation of acyl-CoA to carnitine, increased long-chain acylcarnitine content in VLCAD−/− tissue is expected, but not proven, to be accompanied by increased long-chain acyl-CoA levels. Long-chain acyl-CoA accumulation in tissue may well result in lower mitochondrial respiration via inhibition the mitochondrial adenine nucleotide translocator in the μM range (15).

Abbreviations: CPT, cytosolic carnitine palmitoyltransferase; MS/MS, tandem mass spectrometry; WT, wild type; VLCAD, very long-chain acyl-CoA dehydrogenase

MATERIALS AND METHODS

Reagents

Heptadecanoyl-CoA (C17-CoA) was purchased from Sigma (Deisenhofen, Germany) as Li+ salts and stored at -20°C. Internal standard heptadecanoyl-CoA was prepared by dissolving in methanol to obtain a concentration of 2.5 mM and stored at -80°C until use.

Animals

VLCAD-deficient mice were generated as described in detail previously (7). Experiments were performed on second- to third-generation intercrosses of C57BL6+129sv VLCAD genotypes. Littermates served as controls, and genotyping of mice was performed as described previously (16). Mice were fed with a standard chow diet (MZ Extrudat from sniff® containing 4.5% energy according to the Atwater System) and received tap water ad libitum. As mice are nocturnal animals, treadmill running was performed during the dark cycle. All animal studies were in accordance with the Heinrich-Heine-University Medical Center and Institutional Animal Care and Use Committee guidelines.

Training protocol

Four-month-old WT and VLCAD<sup>−/−</sup> animals ran 120 min on a Columbus Instruments Simplex II metabolic rodent treadmill, consisting of four individual lanes, without inclination, with shock plate incentive (3 Hz, 200 msec, 160 V, 1.5 mA). Mice were placed in an exercise chamber, and after an adaptation period of 15 min, initial belt speed was set to 4 m/min and increased every 5 min by 2 m/min to a maximum of 15 m/min. Mice ran until they displayed signs of exhaustion (>2 s spent on the shocker plate without attempting to reengage the treadmill). To test for long-term alterations in skeletal muscle mitochondrial content, WT and VLCAD<sup>−/−</sup> animals ran for 5 days at an average belt-speed of 8 m/min. The sedentary group consisted of four wild-type and five VLCAD<sup>−/−</sup> animals, and the exercised group consisted of four wild-type and four VLCAD<sup>−/−</sup> animals.

Acyl-CoA analysis

Hind leg skeletal muscle (100–200 mg) was taken up in five volumes of extraction buffer (1:1 iso-propanol / acetonitrile / 10 mM NH₄Ac, pH = 5.0) and minced on ice with scissors. Five volumes of extraction buffer (1:1:1 iso-propanol / acetonitrile / water) were placed in an extraction chamber, and after an adaptation period of 5 min by 2 m/min to a maximum of 15 m/min. Mice ran until they displayed signs of exhaustion (>2 s spent on the shocker plate without attempting to reengage the treadmill). To test for long-term alterations in skeletal muscle mitochondrial content, WT and VLCAD<sup>−/−</sup> animals ran for 5 days at an average belt-speed of 8 m/min. The sedentary group consisted of four wild-type and five VLCAD<sup>−/−</sup> animals, and the exercised group consisted of four wild-type and four VLCAD<sup>−/−</sup> animals.

Acyl-CoA analysis

Hind leg skeletal muscle (100–200 mg) was taken up in five volumes of extraction buffer (1:1 iso-propanol / acetonitrile / 10 mM NH₄Ac, pH = 5.0) and minced on ice with scissors. Five nmols of heptadecanoyl-CoA (C17:0-CoA) were added as internal standard, and the tissue was homogenized using an Ultra-Turrax<sup>®</sup>. Next, the homogenate was centrifuged at 1000 g for 5 min, the supernatant was collected, and the pellet was rehomogenized in five volumes of extraction buffer. The homogenate was centrifuged at 1000 g for 5 min, and the supernatants were pooled. The pooled supernatants were centrifuged at 1000 g for 5 min to remove any remaining cellular debris. For analysis, sample volumes were reduced by approximately 50% using evaporation at 40°C under air.

For LC-tandem MS analysis, a Waters 2795 Alliance HPLC system (Waters, Milford, UK) equipped with a thermostated autosampler was used for solvent delivery and sample introduction. Assay samples were placed in a cooled sample tray, and 20 µl were injected onto a reversed-phase Symmetry C18 column (3.5µm; 7.5 × 4.6 mm; WAT066224; Waters), protected by a guard column (SecurityGuard C18 ODS; 4 × 2.0 mm; Phenomenex). C18:2-CoA, C18:1-CoA, C16:0-CoA, and C17:0-CoA were eluted isocratically with 55% (v/v) acetonitrile in 10 mM NH₄Ac (pH = 6.5) at a flow rate of 0.6 ml/min. The eluate was delivered into a Quattro Micro API tandem mass spectrometer (Micromass, Cambridge, UK) with an ESI probe in positive-ion mode. The waste valve was used to discard early-eluting salts from contaminating the mass spectrometer. The injection interval was 5 min. Nitrogen was used as drying gas at a flow rate of 700 L/h. The collision energy using argon as collision gas was 35 eV. The declustering potential was 45 V, and the ion source temperature was 120°C. Compounds were detected in the multiple-reaction monitoring (MRM) mode. A representative chromatogram, with (A) and without (B) internal standard C17:0-CoA, is shown in Fig. 1. Specific transitions were used for each metabolite, but HPLC separation remained necessary to remove interfering compounds, such as salts, present in muscle extracts, thereby preventing tandem MS apparatus contamination.

Acylcarnitine and carnitine analysis

In tissues, analysis of carnitine and acylcarnitines was performed according to van Vlies et al. (17). Briefly, 50 mg of blotted skeletal muscle was lyophilized for 12 h, including internal standards (16.25 nmoles [2H₃]carnitine and 0.05 nmoles [2H₃]C₁₇₉₉carnitine). The lyophilized tissues were pulverized and dissolved in 1 ml of 80% v/v acetonitrile. After homogenization and centrifugation, the supernatant was dried. Finally, carnitine and acylcarnitines were analyzed by electrospray ionization tandem mass spectrometry as their butyl esters and resuspended in 100 µL ACN/H₂O (50/50% v/v).

Citrate synthase activity

Citrate synthase activity of tissue homogenates was determined to characterize Krebs cycle activity as described previously (18). Samples were assayed in duplicate in flat-bottom microtiter plates, the absorption coefficient was adjusted to the reaction volume (i.e., calculated light path). The media used in the assays were adjusted to 0.1% Triton X-100 to obtain maximal enzyme activities in tissue homogenates.

Cytochrome c oxidase subunit 3 mRNA expression

Expression of mitochondrial DNA encoded cytochrome c oxidase subunit 3 (cox3) mRNA expression was performed as described previously (19) to determine the relative mitochondrial quantity. β-Actin mRNA expression was unaffected by our experimental design and was used as a reference. Cox4 mRNA/cDNA concentrations were normalized for the concentrations of β-actine mRNA/cDNA in the same sample. Values are stated as percent-age of the sedentary control samples.

Protein determination

Protein concentration of tissue homogenates was determined by the BCA assay (Pierce). The BCA reagent was supplemented with 0.1% (v/v) Triton X-100. BSA was used as standard.
Fig. 1. Multiple Reactant Monitoring (MRM) chromatograms of a mouse muscle extracts containing long-chain fatty acyl-CoA esters with (A) and without (B) internal standard C17:0-CoA. Monitored transitions, in order of elution: linoleoyl-CoA (C18:2-CoA): 1030.2 → 523.3; palmitoyl-CoA (C16:0-CoA): 1006.2 → 499.3; oleoyl-CoA (C18:1-CoA): 1032.2 → 525.3; heptadecanoyl-CoA (C17:0-CoA) 1020.2 → 513.3.
Data analysis and statistics

Data were acquired and analyzed using MassLynx NT v4.0 software (Micromass, UK). Data were analyzed with Origin 6.0 (Microcal Software Inc., Northhampton, MA). If not stated otherwise, reported data are presented as arithmetic means ± standard deviation (SD) with *n* denoting the number of animals. Statistical analyses were performed using Student’s *t*-test. Differences between means were considered significant if *P* < 0.05.

RESULTS

Animal condition and mitochondrial content

In contrast to WT mice, VLCAD<sup>−/−</sup> mice had difficulty maintaining a running speed of 15 m/min for the full 120 min, resulting in shorter running times for VLCAD<sup>−/−</sup> mice (Table 1). To stress the mice to their maximal capacity, different running times were needed. Body weights were similar for sedentary WT and VLCAD<sup>−/−</sup> mice (Table 1). Possible proliferation of muscle mitochondria, due to VLCAD-deficiency and/or exercise, was studied by measuring indirect marker enzyme citrate synthase and the expression of cytochrome c oxidase subunit 3 (cox3) mRNA. Muscle citrate synthase activity (in mU · mg protein<sup>−1</sup>) and cox3 expression were not significantly different in WT as well as VLCAD<sup>−/−</sup> mouse skeletal muscle (Table 1).

Muscle acyl-CoA and acylcarnitine content

We first measured muscle acylcarnitine and acyl-CoA content in WT and VLCAD<sup>−/−</sup> mice under sedentary conditions. Overall levels of long-chain acylcarnitines and acyl-CoA were similar in sedentary WT and VLCAD<sup>−/−</sup> muscle, with the exception of muscle C18:1-carnitine content, which was significantly higher in VLCAD<sup>−/−</sup> mice compared with WT mice [11.29 ± 3.26 (n = 5) and 7.01 ± 1.74 (n = 4) nmol · g<sup>−1</sup> wet weight, respectively; *P* < 0.05] (Fig. 2B).

After exercise stress, consisting of treadmill running at 15 m/min, analysis of long-chain acyl-CoAs revealed a significant increase in VLCAD<sup>−/−</sup> muscle [C16:0-CoA, C18:2-CoA, and C18:1-CoA in sedentary VLCAD<sup>−/−</sup>: 5.95 ± 0.74, 4.48 ± 1.14, and 7.70 ± 0.67 nmol · g<sup>−1</sup> wet weight, respectively (n = 5); in exercised VLCAD<sup>−/−</sup>: 8.71 ± 0.84, 9.03 ± 1.86, and 14.82 ± 2.40 nmol · g<sup>−1</sup> wet weight, respectively; *P* < 0.05 (n = 4)] (Fig. 2A). This exercise-induced increase in VLCAD-deficient muscle was paralleled by a similar and significant increase in corresponding acylcarnitines with the same acyl-chain length [C16:0-carnitine, C18:2-carnitine, and C18:1-carnitine in sedentary VLCAD<sup>−/−</sup>: 8.26 ± 3.29, 6.22 ± 2.78, and 11.29 ± 3.27 nmol · g<sup>−1</sup> wet weight, respectively (n = 5); in exercised VLCAD<sup>−/−</sup>: 17.91 ± 4.62, 14.58 ± 3.08, and 26.50 ± 9.16 nmol · g<sup>−1</sup> wet weight, respectively; *P* < 0.05 (n = 4)] (Fig. 2B).

Wild-type mice showed a significant increase in C16:0-carnitine after 2 h of belt running, compared with sedentary palmitoyl-carnitine muscle content [6.64 ± 1.14 and 11.46 ± 1.08 nmol · g<sup>−1</sup> wet weight for sedentary versus exercised WT mice; *P* < 0.05 (n = 4)] (Fig. 2B).

We observed no significant differences between groups in muscle medium-chain octanoyl (C8:0)-carnitine content (data not shown).

Muscle free L-carnitine content

Exercise resulted in lowering of carnitine in both WT and VLCAD<sup>−/−</sup> muscle. This reduction was significant in VLCAD<sup>−/−</sup> mice but not in WT mice [carnitine muscle levels in sedentary and exercised VLCAD<sup>−/−</sup>: 154.3 ± 35.8 (n = 5) and 106.5 ± 13.6 (n = 4) nmol · g<sup>−1</sup> wet weight (*P* < 0.05), respectively; in sedentary and exercised WT: 199.3 ± 40.4 (n = 4) and 134.7 ± 37.0 (n = 4) nmol · g<sup>−1</sup> wet weight, respectively].

DISCUSSION

In the present study, long-chain acylcarnitines and acyl-CoAs were measured to monitor the effect of exercise stress on VLCAD-deficient muscle. We were able to show for the first time that exercise stress, consisting of treadmill running, resulted in a significant, corresponding increase in C16:0, C18:1, and C18:2-carnitine and -CoA in VLCAD<sup>−/−</sup> mouse muscle. Accumulation of long-chain acylcarnitines is well documented and has been implicated in the development of rhabdomyolysis in VLCAD-deficient patients (20). However, it is unknown whether, and to what extent, this increase in long-chain acylcarnitines is mirrored by an increase in acyl-CoA esters of corresponding chain length. The mouse model of VLCAD-deficiency also displays acylcarnitine accumulation in tissues during fasting and exercise stress (16) and is, therefore, a suitable animal model to study the effects of VLCAD-deficiency at a cellular level.

First, we measured if mitochondrial content was altered in exercised VLCAD<sup>−/−</sup> muscle. This is of importance because in heart muscle approximately 95% of the cellular CoA pool is located inside mitochondria (21). Previous studies have shown that mitochondrial density increases in oxidative soleus and heart muscle of VLCAD-deficient

Expressed as citrate synthase activity (mU · mg protein<sup>−1</sup>) and Cox3 mRNA expression (as % of wild-type). VLCAD, very long-chain acyl-CoA dehydrogenase.
was only significant for C18:1-carnitine, an observation also reported by Cox et al. (23). In sedentary VLCAD/−/− muscle, long-chain C16:0, C18:1, and C18:2 acyl-CoA were not increased, compared with WT muscle. The absolute content of long-chain acyl-CoA (in nmol · g−1 wet weight) in WT mouse muscle was comparable to reported values in literature, obtained with both HPLC and mass spectrometry techniques (24–28).

Exercise stress significantly increased long-chain acyl metabolites, with C18:1 chain-length having the most pronounced effect. Elevation of C18:1-carnitine and C18:1-CoA was approximately 4-fold and 3-fold, respectively, in exercised VLCAD/−/− muscle, as compared with sedentary WT muscle. Unlike WT-exercised muscle, all long-chain acyl CoA esters significantly increased in VLCAD/−/− muscle upon exercise (Fig. 2), illustrating the impact of work-load on the VLCAD-deficient phenotype and the extent of activated fatty acid oxidation. In addition, it appears that during periods of elevated workload, the carnitine pool of VLCAD-deficient muscle can no longer adequately scavenge acyl moieties, resulting in a significant increase in muscle long-chain acyl-CoA esters. Importantly, this

Figure 2. Muscle acyl-CoA (A) and acylcarnitine (B) levels in sedentary WT (n = 4) and VLCAD/−/− (n = 5) and exercised WT (n = 4) and VLCAD/−/− (n = 4) mice. Values are means ± SEM. that exercise results in a stronger accumulation of acylcarnitines and acyl-CoA esters may play an important role in disease pathogenesis. Interestingly, detailed histological investigation of VLCAD-deficient heart were accompanied by changes in mitochondrial ultrastructure, an adaptive response also observed in VLCAD−/− mouse heart. These cellular alterations, which included collagen deposition, and vacuolated myocytes, which may be indicative of cytotoxicity (7). These cellular alterations in VLCAD-deficient heart were accompanied by changes in mitochondrial ultrastructure, an adaptive response also observed in VLCAD−/− mouse cells (7). However, it is currently still unknown whether these changes are the direct consequence of accumulating (long-chain) acylcarnitines and acyl-CoA esters. Of note, calculation of absolute cytosolic concentrations based on tissue content (in nmol·g−1) should be treated with caution because free long-chain fatty acid and acyl-CoA concentrations are buffered by fatty acid and acyl-CoA binding proteins inside the cell (30), thereby lowering the concentration on free acyl compounds.

In conclusion, we demonstrate for the first time that long-chain acylcarnitines and acyl-CoA esters increase and directly correlate in VLCAD−/− mouse muscle after exercise. However, the question whether exercise-induced accumulation of acyl esters is an important factor in disease pathogenesis cannot be answered at this time.

The authors thank Dr. M.D. Laryea, Department of General Pediatrics, Heinrich-Heine-University, Duesseldorf, Germany, for expert advice on liquid-chromatography analysis. We are grateful to Mrs. G. Schmitz and Mr. A. Vogt for technical assistance.
